In this paper, we study robust stability of sparse LTI systems using the stability radius (SR) as a robustness measure. We consider real perturbations with an arbitrary and pre-specified sparsity pattern of the system matrix and measure their size using the Frobenius norm. We formulate the SR problem as an equality-constrained minimization problem. Using the Lagrangian method for optimization, we characterize the optimality conditions of the SR problem, thereby revealing the relation between an optimal perturbation and the eigenvectors of an optimally perturbed system. Further, we use the Sylvester equation based parametrization to develop a penalty based gradient/Newton descent algorithm which converges to the local minima of the optimization problem. Finally, we illustrate how our framework provides structural insights into the robust stability of sparse networks.

1. Introduction

Guaranteed stability under parameter uncertainty is one of the central problems in robust design of dynamical systems. Consider the following Linear Time-Invariant (LTI) dynamical system

\[ \dot{x}(t) = Ax(t), \]

where \( x \in \mathbb{R}^n \) is the state, \( A \in \mathbb{R}^{n \times n} \), and \( \mathcal{D} \) can either be the continuous-time differential operator (i.e., \( \mathcal{D}x(t) = \dot{x}(t) \)) or the discrete-time shift operator (i.e., \( \mathcal{D}x(t) = x(t+1) \)). Let the complex plane \( \mathbb{C} \) be divided into any two disjoint sets as \( \mathbb{C} = \mathbb{C}_+ \cup \mathbb{C}_- \), where \( \mathbb{C}_- \) is open. Stability of (1) requires the eigenvalues of \( A \) to lie in the stability region \( \mathbb{C}_+ \). Assuming that \( A \) is stable, the robust stability analysis of (1) involves characterizing the eigenvalues of the affine perturbations of \( A \) given by

\[ A \rightarrow A(\Delta) \triangleq A + B \Delta C, \]

where \( \Delta \in \mathbb{R}^{m \times p} \) is the perturbation matrix and \( B \in \mathbb{R}^{n \times m} \). \( C \in \mathbb{R}^{p \times n} \) are structure matrices. The perturbed matrix \( A(\Delta) \) can also be interpreted as the closed loop matrix of the following linear system

\[ \mathcal{D}x(t) = Ax(t) + Bu(t), \]

\[ y(t) = Cx(t), \]

with static feedback \( u(t) = \Delta y(t) \).

There have been numerous studies on eigenvalue characterization and stability of the perturbed matrix (2) (see Hinrichsen & Pritchard, 2005 for a comprehensive treatment). However, an inherent crucial assumption in these studies (and of the robust stability theory) is that all entries of the perturbation \( \Delta \) are allowed to be freely perturbed. Clearly, this assumption is not applicable in modern control systems which are increasingly networked and distributed in nature and, as a result, exhibit a specific sparsity structure. In such systems, the matrix \( A \) typically has an associated sparsity pattern, and its certain entries are fixed/zero, and it is feasible to perturb only the non-fixed entries of \( A \). Therefore, the perturbations \( \Delta \) applied to \( A \) cannot be chosen freely and must satisfy certain sparsity constraints as well.

In this paper, we develop a novel framework to study the robust stability of LTI systems with sparsity constraints. Let \( S \in \{0,1\}^{m \times p} \) be a binary matrix that specifies the sparsity structure of the perturbation \( \Delta \). Specifically,

\[ \Delta_{ij} = \begin{cases} 0 & \text{if } S_{ij} = 0, \text{ and} \\ \ast & \text{if } S_{ij} = 1, \end{cases} \]

where \( \ast \) denotes any real number. Further, let \( \Delta_S \) denote the set of sparse perturbations given by

\[ \Delta_S = \{ \Delta \in \mathbb{R}^{m \times p} : S \circ \Delta = 0 \}, \]

where \( S^c \triangleq 1_{m \times p} - S \) denotes the complementary sparsity structure matrix and \( \circ \) denotes the Hadamard (element-wise) product. We consider the notion of Stability Radius (SR) as the measure of robust stability, which is the minimum-size real perturbation...
that moves an eigenvalue(s) of $A(\Delta)$ outside the stability region. Formally, the SR is defined as
\[ r \triangleq \inf \{ \| \Delta \| : \Gamma(A(\Delta)) \cap C_0 \neq \emptyset, \ \Delta \in \Delta_S \}, \]
where $\Gamma(\cdot)$ denotes the spectrum of a matrix, and $\| \cdot \|$ can be the spectral or Frobenius norm (see the discussion in next paragraph). The SR provides a worst case measure for the robustness of the system in the sense that all perturbations with $\| \Delta \| < r$ are guaranteed to preserve the stability of the perturbed system. Note that while matrices $B$ and $C$ can be chosen to impose certain perturbation structures on $A$ (such as zero column(s) or row(s)), they cannot capture arbitrary sparsity constraints. Thus, we require the explicit sparsity constraint $\Delta \in \Delta_S$ in (4).

The perturbation size $\| \Delta \|$ can be measured using the spectral norm or Frobenius norm, and these respective cases are referred to as $2$-norm SR and $F$-norm SR. The case when $\Delta$ is allowed to be complex is referred to as complex SR. The case $B = C = I$ and $\Delta_S = \mathbb{R}^{m \times p}$, where each entry of $A$ is allowed to be perturbed independently, is referred to as unstructured SR. In this paper, we study the sparse, real, $F$-norm SR problem by formulating it as an equality-constrained optimization problem. The real SR problem is more suitable for engineering applications where the dynamics matrix $A$ and its perturbations are typically real. Further, unlike the spectral norm, the Frobenius norm explicitly measures the entry-wise perturbations of $\Delta$, which is useful in characterizing the size and structure of sparse perturbations.

**Related work** The stability radius problem without sparsity constraints has a rich history. Although robust stability problems have been studied in various forms in the past, the notion of $2$-norm stability radius was introduced formally in Hinrichsen and Pritchard (1986a, 1986b). Various bounds and characterizations of unstructured, complex, and real SRs were given in Hinrichsen and Pritchard (1986a) and Van Loan (1985). In Hinrichsen and Pritchard (1986b), characterizations of structured, complex SR were presented in terms of the $H_\infty$-norm of the associated transfer function and solutions of parameterized algebraic Riccati equations. Bisection algorithms to compute the complex SR were presented in Byers (1988) and Hinrichsen, Kelb, and Linnemann (1989) and algorithms to compute the $H_\infty$-norm were given in Boyd, Balakrishnan, and Kabamba (1989), Boyd and Balakrishnan (1990) and Bruinsma and Steinbuch (1990). Since the optimal perturbation for the complex SR problem always has rank $1$ (Hinrichsen & Pritchard, 2005), the $2$-norm and the $F$-norm SRs are equal for the complex case.

The real SR problem is considerably more difficult than its complex counterpart (Hinrichsen & Pritchard, 1986a). Qiu et al. presented several lower bounds for the unstructured case in Qiu and Davison (1991, 1992) and a complete algebraic characterization of the structured case was presented in Qiu et al. (1995). Based on this characterization, a level-set algorithm was developed in Sreedhar, Van Dooren, and Tits (1996) for the structured case and an implicit determinant method was provided for the unstructured case in Freitag and Spence (2014). For a comprehensive treatment of the $2$-norm SR problem, see Hinrichsen and Pritchard (2005, Chapter 5).

While the $2$-norm SR problem has been studied extensively, there are limited studies on the $F$-norm SR problem. Note that due to the fundamental difference between the spectral and Frobenius norms, the procedure in Qiu et al. (1995) to characterize the real, $2$-norm SR cannot be used to characterize the real, $F$-norm SR. In Bobylev, Bulatov, and Diamond (1999, 2001), lower bounds on the real, $F$-norm SR were provided for the unstructured and structured cases, respectively. Recently, a number of works have appeared that use iterative algorithms to approximate the $2$-norm/$F$-norm real SR (Guglielmi, 2016; Guglielmi, Gurbuzbalaban, Mitchell, & Overton, 2017; Guglielmi & Lubich, 2013; Guglielmi & Manneta, 2015; Rostami, 2015). Typically, these algorithms use two levels of iterations. The inner iteration approximates the rightmost (outermost, for discrete-time case) points of spectral value sets, and the outer iteration verifies the intersection of these points with the stability boundary. All of these aforementioned studies consider the non-sparse SR problem.

In a very recent paper (Johnson, Wicks, Zefran, & DeCarlo, 2018), which was developed independently and concurrently with our paper, the authors study the structured distance of an LTI system from the set of systems that do not exhibit a general property $\mathcal{P}$, such as controllability, observability, and stability. They provide necessary conditions for a locally optimal perturbation and develop an algorithm to obtain such solution. Since the framework in Johnson et al. (2018) is developed for a general class of problems, the provided necessary conditions are implicit in terms of abstract linear maps. On the other hand, we use a different approach to obtain stronger and explicit necessary conditions for the sparse SR problem. In addition, we provide sufficient conditions for a local minimum, thereby completely characterizing the local minima. Finally, our gradient/Newton descent algorithm is simpler than the algorithm proposed in Johnson et al. (2018).

**Contributions** The contribution of the paper is two-fold. First, we propose a novel approach to compute the sparse SR by formulating the SR problem as an equality-constrained minimization problem. We characterize its local optimality conditions, thereby revealing important geometric properties of the optimal perturbed system. Second, using the Sylvester equation based parameterization, we develop a penalty-based gradient algorithm to solve the optimization problem that is guaranteed to converge to a local minimum. Numerical studies are included to illustrate various properties of the optimal perturbations and the algorithm, and to highlight the usefulness of the framework for sparse networks.

**Paper organization** In Section 2 we present our mathematical notation and some properties that we use in the paper, and formulate the SR problem as an optimization problem with equality constraints. Section 3 contains the local optimality conditions of the SR problem. In Section 4 we develop a gradient based algorithm to compute local solutions. Numerical examples are presented in Section 5. Finally, we conclude the paper in Section 6.

### 2. Problem formulation

#### 2.1. Mathematical notation and properties

We use the following notation throughout the paper: $\| \cdot \|_f$ and $\| \cdot \|_2$ denote the Frobenius and spectral norm of a matrix, respectively. $\circ$ and $\otimes$ denote the Hadamard and Kronecker product, respectively. The identity matrix is denoted by $I$. $\Gamma(\cdot)$, $(\cdot)^T$ and $\text{tr}(\cdot)$ denote the spectrum, transpose and trace of a matrix, respectively. $(\cdot)^+ \text{ and } (\cdot)^{-}$ denote the pseudo-inverse and spectral abscissa of a matrix, respectively. A positive-definite matrix $A$ is denoted by $A > 0$. $x^*$ and $x^T$ denote the complex conjugate and the conjugate transpose, respectively, of a vector. $x.e(\cdot)$ and $\text{Im}(\cdot)$ denote the real and imaginary parts of a complex number, respectively. $\text{vec}(\cdot)$ denotes the vectorization of a matrix $\text{diag}(\cdot)$ denotes a $n \times n$ diagonal matrix with diagonal elements given by $a \in \mathbb{R}^n$, $1_{m \times n}$ denotes a $m \times n$ matrix of all ones. Finally, $j = \sqrt{-1}$ denotes the unit imaginary number.

We use the following mathematical properties for the derivation of our results (Magnus & Neudecker, 1999; Petersen & Pedersen, 2012):

\[ P.1 \quad \| A \|_F^2 = \text{tr}(A^T A) = \text{vec}(A)^T \text{vec}(A), \]
However, we have omitted this constraint in SR eigenvalues of minimum distance problems (Kressner & Voigt, 2015). As a result, the optimization problem SR solution of the spectral constraint in (6) in terms of an eigenvalue–eigenvector pair \((\lambda, \phi)\). The normalization constraint (7b) is added to ensure uniqueness of the eigenvector (up to unitary scaling). The sparsity constraint (7c) is a reformulation of \(\Delta \in \Delta_c\) (cf. (3)).

Several remarks are in order for the optimization problem SR. First, the eigenvalue–eigenvector constraint (7a) is not convex. As a result, the optimization problem SR is not convex, and it may have multiple local minima. This is a typical property of all 2-norm/F-norm, complex/real SR problems, as well as most other minimum distance problems (Kressner & Voigt, 2015).

Second, besides assigning an eigenvalue(s) on the imaginary axis, the equality constraint in (6) also requires the remaining eigenvalues of \(A(\Delta)\) to lie in the open left-half complex plane.

However, we have omitted this constraint in SR because it will be inherently satisfied by the global minimum of SR due to (i) Assumption A1, (ii) the continuity properties of the eigenvalues of \(A(\Delta)\), and (iii) the definition of SR in (6). However, a local minimum of SR need not satisfy this constraint necessarily. Thus, all the local minima \(\Delta\) of SR should be verified against the constraint \(\alpha(A(\Delta)) = 0\) (see Section 5 for an example).

Third, it may be possible that SR is non-feasible and there does not exist any \(\Delta\) that satisfies constraints (7a)–(7c). Such non-feasible cases are universally robust in the sense that no perturbation with the given sparsity structure can make the system unstable, and thus \(r_c = \infty\). To avoid such cases, we make the following assumption:

**A2:** SR is feasible, i.e., there exists at least one perturbation \(\Delta\) that satisfies (7a)–(7c).

Finally, since \(\alpha(\Delta)\) is real, its eigenvalues are symmetric with respect to the real axis. Hence, if \(\hat{\Delta}, \hat{\phi}, \hat{x}\) is a local minimum of (7), then \((\Delta, -\hat{\phi}, \hat{x}^\top)\) is also a local minimum.

Let \(S \triangleq \text{vec}(\Delta) \in \mathbb{R}^{mn}\) and let \(n_s\) denote the number of non-trivial sparsity constraints (i.e., number of 1’s in \(S^c\)). Then, (7c) can be vectorized as:

\[ S \in \{0, 1\}^{n \times n_s} \]

where \(S \in \{0, 1\}^{n \times n_s}\) is a binary matrix given by \(S = [s_{11}, s_{12}, \ldots, s_{n_s}]^\top\) with \(s_{11}, \ldots, s_{n_s} = \text{supp}(\text{vec}(S))\) being the set of column indices indicating the 1’s in \(S^c\) and \(e_i\) being the \(i\)th standard basis vector of \(\mathbb{R}^{mn}\). Next, we present an algebraic condition to verify Assumption A2. We omit the proof, which follows from vectorizing (7a).

**Lemma 2.1 (Feasibility).** The optimization problem (7) is feasible if and only if there exist \(x \in \mathbb{C}^n\) and \(\omega \in \mathbb{R}\) satisfying: \((A - j\omega) x \in \text{Range}(\{[\text{Re}(C)^\top \otimes B][I - S^\top S]\})\), where \(\text{Range}()\) denotes the column space of a matrix over the field of real numbers.

**3. Solution to the optimization problem.**

In this section we present the optimality conditions for the local solutions of the optimization problem SR, and characterize an optimal perturbation. We use the theory of Lagrange multipliers for equality-constrained minimization to derive the optimality conditions. We begin with the following assumption:

**A3:** Let \((\hat{\Delta}, \hat{\phi}, \hat{x})\) be a local minimum of SR. Then, \(\hat{\phi} \neq 0\).

Assumption A3 is necessary to differentiate between the cases when constraint (7a) is complex or real (if \(\hat{\phi} = 0\)). We present the analysis for the complex case and will discuss the real case later in this section (see Remark 2).

**Remark 1 (Complex Variables).** Since \(x\) may be a complex variable, the constraint (7a) also induces the following conjugate constraint:

\[ (A + B\Delta) x^\ast = -j\omega x^\ast. \]

(9)

We use the formalism wherein a complex number and its conjugate are treated as independent variables (Brandwood, 1983; Hjärengnes & Gesbert, 2007) and, thus, we treat \(x^\ast\) and \(x^\ast\) as independent variables.

In the theory of equality-constrained optimization, the first-order optimality conditions are meaningful only when the optimal point satisfies the following regularity condition: the Jacobian of the constraints, defined by \(J_n\), has full rank. This regularity condition is mild and usually satisfied for most classes of problems (Luenberger & Ye, 2008). Before presenting the main result, we derive the Jacobian, which depends on the ordering of the constraints and the variables. Recalling Remark 1, let \(z \triangleq [x^\ast, x^\ast, \omega^\ast]\) be the vector containing all the variables of optimization problem SR.

---

1 A trivial example is: \(A = [1 -j2, 0], B = C = I_2\), and \(S = [0 1]_2\). In this case, since only \(A_{12}\) is allowed to be perturbed, the eigenvalues of \(A(\Delta)\) will always be \([-1, -2]\) and cannot lie on the imaginary axis.
Lemma 3.1 (Jacobian of the Constraints). The Jacobian of the equality constraints (7a), (9), (7b), (8) is
\[
J_h(z) = \begin{bmatrix}
A(\Delta) - j oI & 0 & (Cz)^T \otimes B & -j x^T \\
0 & A(\Delta) + j oI & (Cx^*)^T \otimes B & j x^* \\
X^h & X^l & 0 & 0 \\
0 & 0 & S & 0
\end{bmatrix}.
\]

Proof. We construct the Jacobian \(J_h\) by taking the derivatives of the constraints (7a), (9), (7b), and (8) with respect to \(z\). Using P.3, constraint (7a) can be written as
\[
(A - joI)x + [(Cx)^T \otimes B] \delta = 0.
\]
Differentiating (7a) w.r.t. \(x, \omega\) and (10) w.r.t. \(\delta\) yields the first (block) row of \(J_h\). Similar derivatives of the conjugate constraint (9) w.r.t. \(z\) yields the second (block) row of \(J_h\). Differentiating constraint (7b) w.r.t. \(x\) and \(x^*\) yields the third (block) row of \(J_h\). Finally, differentiating (8) w.r.t. \(z\) yields the last (block) row of \(J_h\). \(\Box\)

Next, we provide the local optimality conditions for the optimization problem SR.

Theorem 3.2 (Optimality Conditions). Let \((\Delta, \hat{x}, \hat{\omega})\) (equivalently \(\hat{z} = [\hat{x}^T, \hat{\omega}^T, \hat{x}^*, \hat{\omega}^*]^T\)) satisfy the constraints (7a)–(7c), and let \(\hat{l}\) denote the left eigenvector of \(A(\Delta)\) corresponding to the eigenvalue \(j o\). Let \(J_h(z)\) be defined in Lemma 3.1, and let \(P(z) = I - J_h^T(z)J_h(z)\). Further, let \(\tilde{N} \triangleq C \otimes (B^T)\), and let
\[
\tilde{D} \triangleq \begin{bmatrix}
0 & 0 & \tilde{N}^h & \hat{j} \hat{l} \\
0 & 0 & \tilde{N}^* & -\hat{j} \hat{l} \\
\tilde{N} & \tilde{N}^* & 2I & 0 \\
-\hat{j} \hat{l} & \hat{j} \hat{l} & 0 & 0
\end{bmatrix}.
\]

Then, \((\Delta, \hat{x}, \hat{\omega})\) is a local minimum of the optimization problem SR if and only if
\[
\hat{\omega} = -S \circ [B^T \text{Re}(\hat{z}^*)C]^T, \quad (A + B\Delta C)X = j o\hat{x}, \quad (A + B\Delta C)^*^T = j o\hat{l}, \quad \text{Im}(\hat{x}) = 0, \quad J_h(z) \text{ has full rank}, \quad P(z)DP(z) > 0.
\]

Proof. We prove the result using the Lagrange multiplier method for equality-constrained minimization. Let \(l \in \mathbb{C}^n, \Gamma, \mathbf{h} \in \mathbb{R}\) and \(M \in \mathbb{R}^{m \times p}\) be the Lagrange multipliers associated with constraints (7a), (9), (7b) and (7c), respectively. The Lagrangian function is given by
\[
L \triangleq \frac{1}{2} \text{tr}(\Delta^T \Delta) + h(X^h x - 1) + \frac{1}{2} l^T(A + B\Delta C - j oI)x + \frac{1}{2} l^T(A + B\Delta C + j oI)x^* + \text{tr}(M \circ \{S^c \circ \Delta\}I_p).
\]

Part 1 – First-order necessary conditions (11a)–(11e). Differentiating \(L\) w.r.t. \(x\) and setting to 0, we get
\[
\frac{d}{dx}L \triangleq \frac{1}{2} l^T(A + B\Delta C - j oI) + hX^h = 0
\]
and thus, from (12), we get (11c). Eq. (11b) is a restatement of (7a) for the optimal \((\Delta, \hat{x}, \hat{\omega})\). Differentiating \(L\) w.r.t. \(\Delta\) and setting to 0, we get
\[
\frac{d}{d\Delta}L \triangleq \Delta + \text{Re}(B^T l^x C^T) + M \circ S^c = 0.
\]
Taking the Hadamard product of (13) with \(S^c\), and using (7c) and \(S^c \circ S^c = S^c\), we get
\[
S^c \circ \text{Re}(B^T l^x C^T) + M \circ S^c = 0.
\]
Replacing \(M \circ S^c\) from (14) in (13), we get (11a). Finally, differentiating \(L\) w.r.t. \(\omega\) and setting to 0, we get
\[
\frac{d}{d\omega}L \triangleq \frac{1}{2} l^T l^x - \frac{1}{2} l^T x = \text{Im}(l^T x) = 0.
\]
Eq. (11e) is the necessary regularity condition and follows from Lemma 3.1.

Part 2 – Second-order sufficient condition (11f). We compute the Hessian (denoted by \(D\)) of \(L\) w.r.t. \(z\) by expressing the second-order differential of \(L\) as \(d^2 L = dz^T Ddz\) (cf. P.8). Taking differential of \(L\) twice, we get
\[
d^2 L \triangleq \text{tr}[(d\Delta)^T \Delta] + l^T B(d\Delta)Cx - j o(d\omega)l^T (dx) + \text{tr}B(d\Delta)C(dx^*) + j o(d\omega)l^T (dx^*) + 2h(dx)^T (dx),
\]

iff \(y = P(z)\) for a complex \(s\), where \(P(z)\) is the projection matrix onto the null space of \(J_h(z)\) (Luenberger & Ye, 2008). Since the projection matrix \(P(z)\) is symmetric, (11f) follows. \(\Box\)

The local optimality conditions in Theorem 3.2 reveal the inherent properties of an optimal perturbation and the stability radius. First, (11a) presents the explicit relations between the optimal perturbation \(\Delta\) and left and right eigenvectors of the optimally perturbed matrix \(A(\Delta)\). Second, (11d) shows that the inner product of the left-conjugate and right eigenvectors of the optimal perturbation is always real. Third, notice that the optimal perturbation in (11a) always satisfies the sparsity constraint (7c) (since \(S \circ S^c = 0\)). The optimality condition (11a) can also be re-written as \(\Delta = -S \circ [B^T \hat{X}^*^T C^T]\), where \(\hat{X} \triangleq [\text{Re}(\hat{l}), -\text{Im}(\hat{l})]\) and \(\hat{X} \triangleq [\text{Re}(\hat{x}), \text{Im}(\hat{x})]\). This shows that, although \(\text{rank}(B^T \hat{X}^*^T C^T) \leq 2\), the rank of \(\Delta\) can be greater than 2. In contrast, the optimal perturbation for real, non-sparse, 2-norm/F-norm SR always has rank less that or equal to 2 (Qiu et al., 1995).

Remark 2 (Optimality at \(\hat{\omega} = 0\)). If \(\hat{\omega} = 0\) (Assumption A3 is violated), a similar analysis can be performed to compute the optimality conditions by using the following real eigenvalue assignment equation instead of (7a)
\[
(A + B\Delta C)x = 0,
\]
where \(x \in \mathbb{R}^n\). \(\Box\)
Next, we present a brief comparison of our optimality conditions with those in Johnson et al. (2018). Since Johnson et al. (2018) considers perturbations of the form $A - \Delta$, we assume $B = -C = -I$. In the current setting, condition (1a) of Theorem 1 in Johnson et al. (2018) becomes: $\Delta$ is a real matrix that satisfies the sparsity constraints (7c) and is the minimum-norm matrix that minimizes $\|T^T \Delta x - T(A - \Delta 0)x\|_F$. Further, condition (1b) in Johnson et al. (2018) can be stated as follows: $d \omega$ where $d \omega$ minimizes $\|D(d\omega) - \Delta\|_F$ and $D(d\omega)$ is a real matrix that satisfies the sparsity constraints (7c) and is the minimum-norm matrix that minimizes $\|T^T \Delta x - T(A - \Delta 0)x\|_F$. We can observe that the above conditions are implicit and involve solving optimization problems, whereas our conditions (11a)–(11d) are more explicit.

The solution of the optimization problem SR can be obtained by numerically/iteratively solving the optimality equations (11a)–(11d) using any non-linear equation solving technique. The regularity and local minimum property of the solution can be verified using (11e) and (11f), respectively. Finally, the local minimum should be verified against $a(\hat{A}(\Delta)) = 0$. Since the optimization problem is not convex, only local minima can be obtained via this procedure. To improve upon the local solutions and to capture the global minimum, the above procedure can be repeated for different initial conditions. Clearly, finding the global minimum is not guaranteed in all cases. In this case, the procedure provides an upper bound to the SR.

Instead of solving the optimality equations, we use a penalty based approach using gradient descent to obtain the local solutions. Details of this approach and the corresponding algorithm are provided in the next section.

### 4. Gradient based solution algorithm

In this section, we present an iterative gradient based algorithm to obtain a local solution to optimization problem SR. We use the penalty based optimization approach and the Sylvester equation based parametrization to convert the constrained optimization problem (7) into an unconstrained optimization problem. Note that we ignore the eigenvector normalization assumptions.

Using the penalty based optimization approach (Luenberger & Ye, 2008), we modify the cost function to include a penalty when the sparsity constraints are violated. The penalty is imposed by weighing individual entries of the perturbation using a weighing matrix $W \in \mathbb{R}^{m \times p}$ given by $W_{ij} = \begin{cases} 1 & \text{if } S_{ij} = 1, \\ \infty & \text{if } S_{ij} = 0. \end{cases}$ Using the weighing matrix $W$, the penalized cost is $J_W = \frac{1}{2} \|W \circ \Delta\|_F^2$. Next, we reformulate (7a) as a purely real constraint. Let $X = \begin{bmatrix} \Re(x) \\ \Im(x) \end{bmatrix} \in \mathbb{R}^{n \times 2}$. Then, (7a) is equivalent to

$$\begin{bmatrix} A + B \Delta C \end{bmatrix} X = \omega \tilde{X},$$

where $\tilde{\Delta} = \begin{bmatrix} A \\ \Delta C \end{bmatrix}$. Next, we use the Sylvester equation based parametrization (Bhattacharyya & De Souza, 1982) and define $G = \Delta CX \in \mathbb{R}^{m \times 2}$. It follows that (16) is equivalent to

$$AX - \omega X = -BG,$$

$G = \Delta CX.$

Note that (16) is a Sylvester equation in $X$. Due to Assumption A1, $\Gamma(A) \cap \Gamma(-\omega B) = \emptyset$ and thus, (16) has a unique solution for any given $(G, \omega)$. Further, for any $(G, \omega)$, (17a) has a solution if $CX \in \mathbb{R}^{p \times 2}$ has rank two. Thus, we make the following assumption.

**A4:** For any $(G, \omega)$, $CX$ has full column rank, where $X$ is the unique solution of (17a). This requires $p \geq 2$.

For a given $(G, \omega)$ and under Assumption A4, we can solve (17b) to obtain $\Delta$, which, in general, may not be unique. Since we aim to minimize the norm of the weighted perturbation $(W \circ \Delta)$, we choose $\Delta$ as the solution of the following quadratic optimization problem: $\min_{\Delta \in \mathbb{R}^{m \times n}} \frac{1}{2} \|W \circ \Delta\|_F^2$ (17b) holds.

Thus, the constrained optimization problem (7) can be reformulated as the following optimization problem in free variables $G, \omega$:

$$\min_{G \in \mathbb{R}^{m \times 2}, \omega \in \mathbb{R}} J_w = \frac{1}{2} \|W \circ \Delta\|_F^2$$

s.t. (17a), (19a) and (19b) hold.

We aim to solve problem (20) using a gradient descent approach. The next result provides analytical expressions for the gradient and Hessian of the cost in (20). Let $\gamma = \text{vec}(G) \in \mathbb{R}^{2m \times n}$, $\gamma = \text{vec}(X) \in \mathbb{R}^{2n}$, $\lambda = \text{vec}(A) \in \mathbb{R}^{2n}$, and let the free variables of (20) be denoted by $\hat{\xi} \in \mathbb{R}^l$. Further, let $e_{2m+1} = [0, \ldots, 0, 1]^T \in \mathbb{R}^{2m+1}$ and $W \in \text{diag}([\text{vec}(W \circ W)])$.

**Lemma 4.1 (Gradient and Hessian).** Define the following Kronecker products:

$$\hat{B} = I_2 \otimes B, \quad \hat{I} = I_1 \otimes I_n, \quad \hat{A}(\omega) = I_2 \otimes A + \omega \hat{I},$$

$$\hat{\Delta} = I_2 \otimes (\Delta C), \quad \hat{X} = (C X)^T \otimes I_m, \quad \hat{X} = \begin{bmatrix} \tilde{X}^T & \tilde{X} \end{bmatrix},$$

and $E = [(C \otimes A) T_{m,2}]^T$. Let $U = [U_1 \quad U_2]$ and $V$ be the unique solutions of, respectively,

$$U \hat{X} = [e_{2m}^T] 0, \quad \text{and } \hat{A}(\omega) V = [\hat{B} \quad \hat{I} X].$$

Further, let $\hat{U}_1 \in \mathbb{R}^{m \times p}$ and $\hat{U}_2 \in \mathbb{R}^{m \times 2}$ be such that vec($\hat{U}_1$) = $U_1^T \hat{W} \delta$ and vec($\hat{U}_2$) = $U_2^T \hat{W} \delta$. Define $\hat{Y} = \begin{bmatrix} 0 & 0 \\ \delta \end{bmatrix} + EV, Z = (U Y)^T$, and $M = \hat{V}^T \begin{bmatrix} \hat{U}_1^T \otimes C^T & T_{2,n}(C^T \hat{U}_1 \otimes I_2) T_{m,2} \end{bmatrix} \hat{X}^{-1} \hat{Y} - \hat{V}^T \hat{A}(\omega)^{-1} \hat{E}^T \hat{U} \delta \delta_{2m+1}$.

Then, the gradient and Hessian of $J_w$ in (20) satisfy

$$\frac{dJ_w}{d\hat{\xi}} = Z \hat{W} \delta, \quad \text{and } \frac{d^2J_w}{d\hat{\xi}^2} = H = Z \hat{W} Z^T + M + M^T.$$

**Proof.** See the Appendix.

Using Lemma 4.1, we present a gradient/Newton descent Algorithm 1 to solve the optimization problem (20).
The complexity of step 1 can be computed in \( O(n^3) \). In step 3, \( \Delta \) (and \( \lambda \)) can be obtained by vectorizing (19a)-(19b) (see (26) in the Appendix), and its complexity is \( O(m^p) \).

Remark 3 (Algorithm when \( \omega = 0 \).) The perturbation \( \Delta \) computed at each iteration of Algorithm 1 assigns two eigenvalues of \( A(\Delta) \) at \( \pm j\omega \). As a consequence, in cases where \( \omega = 0 \) is a local minimum of (20), the algorithm converges to a local minimum \( \Delta \) such that \( A(\Delta) \) has eigenvalue 0 with multiplicity two. This may not be a desired local minimum since instability results from at least one (and not necessarily two) eigenvalue of \( A(\Delta) \) being at the origin. In this case, we can use (15) instead of (16) to develop an analogous algorithm.

Remark 4 (Choice of Weights). As the weight \( w \) increases, an optimal solution of (20) satisfies the sparsity constraints (7c) with increasing accuracy. However, an increase in the weights also reduces the convergence speed of Algorithm 1. Thus, there exists a trade-off between the accuracy of the sparse solutions and the convergence time of the algorithm.

Remark 5 (Alternative Optimization Techniques). We emphasize that more sophisticated and efficient optimization procedures to solve the \( \text{SR} \) problem can be used. For instance, alternative choices of the Hessian modification term \( V \) that result in better conditioning can be used. Quasi-Newton methods like BFGS (Luenberger & Ye, 2008) to compute approximate Hessian using the expressions in Lemma 4.1 can also be employed. Augmented Lagrangian methods that provide accurate solutions can be explored. Software packages like GRANSO (Curtis, Mitchell, & Overton, 2017) and low-rank solvers for Sylvester equations (Benner, Kohler, & Saak, 2011) can be used for large-scale problems. A detailed study of these methods is not the primary focus of this paper, and is left as the subject of future research.

5. Simulation studies

In this section, we present numerical simulation studies of our algorithm. We perform the simulations using MATLAB R2019a installed on Macbook Pro 2019 with Intel Core i5 processor and 16 GB of RAM. To begin, we consider the following example from Qiu et al. (1995):

\[
A = \begin{bmatrix}
    79 & 20 & -30 & -20 \\
    -41 & -12 & 17 & 13 \\
    167 & 40 & -60 & -38 \\
    33.5 & 9 & -14.5 & -11
\end{bmatrix}, \quad B = \begin{bmatrix}
    0.2190 & 0.9347 \\
    0.0470 & 0.3835 \\
    0.6789 & 0.5194 \\
    0.6793 & 0.8310
\end{bmatrix},
\]

\[
C = \begin{bmatrix}
    0.0346 & 0.5297 & 0.0077 & 0.0668 \\
    0.0535 & 0.6711 & 0.3848 & 0.4175
\end{bmatrix}.
\]

The eigenvalues of \( A \) are \((-1 \pm j, -1 \pm 10i)\). We consider two cases:

Case 1: No sparsity constraints, i.e., \( S = \{1, 1\} \).

Case 2: Only the diagonal entries of \( A \) are allowed to be perturbed, i.e., \( S = \{1\} \).

The weight in the weighing matrix \( W \) is chosen as \( w = 100 \). Table 1 shows the local minima of optimization problem (7) obtained by Algorithm 1 for both the cases. The first local minimum is also the global minimum for both the cases. The initial conditions are randomly selected as \( \omega_{0,gl} = 2.5 \) and \( G_{0,gl} = 1.0582 \quad 1.4115 \)

\[
0.4363 -0.0146
\]

for the global minima for both cases, and as \( \omega_{0,lo} = 1 \) and \( G_{0,lo} = \begin{bmatrix} 0.5201 & -0.0348 \\ -0.0200 & -0.7982 \end{bmatrix} \) for the local minima for both cases. The stopping criteria for all simulations in this section are \( \Delta_{\text{final}} \leq 10^{-5} \) and the maximum number of iterations is set at 1000. Note that the second local minimum for case 1 satisfies \( \alpha(A(\Delta(2))) = 0 \), whereas the second local minimum for case 2 does not satisfy this constraint (c.f. discussion after (7c)). Thus, it is not a valid local minimum.

Next, we illustrate the relation between the local minima of our optimization problem and the geometry of the spectral value sets. Spectral value set captures the region in which all possible eigenvalues of the perturbed system matrices can lie, and for \( \eta \geq 0 \), is defined as:

\[
S_\eta = \{ \Gamma(A + B\Delta C) : \|\Delta\|_F \leq \eta, \Delta \in \Delta_s \}.
\]

Fig. 1 shows the spectral value sets in the complex plane corresponding to the local minima in Table 1. We observe that the local minima are precisely the cases when the \( \text{locally} \) right-most points of the spectral value sets\(^3\) intersect with the imaginary axis.

Fig. 2 presents a sample run of Algorithm 1 for the case 2 of the above example. It is initialized with \( \omega_{0,gl} \) and \( G_{0,gl} \) and takes 24 iterations to converge to the global minimum using the Newton descent steps. Fig. 2 shows the penalized cost (scaled), spectral abscissa of the perturbed matrix \( A(\Delta) \), and \( \omega \) at each iteration. Observe that, at the start of the algorithm, \( \alpha(A(\Delta)) > 0 \) indicating that \( A(\Delta) \) has two eigenvalues in the right-half complex plane (the other two are at \( \pm j\omega_0 \)). As iterations progress, these unstable eigenvalues move towards the left-half plane and, at the global minimum, all eigenvalues are in closed left-half plane (c.f. discussion after (7c)). Further, the optimization cost decreases monotonically during the iterations.

\(^3\) \( \Delta_s \) for this example was visualized by performing an exhaustive search over \( \Delta = \begin{bmatrix} \Delta_{11} & 0 \\ 0 & \Delta_{22} \end{bmatrix} \) such that \( \Delta_{11}^2 + \Delta_{22}^2 \leq \eta^2 \), and plotting \( \Gamma(A(\Delta)) \).
optimal perturbation as a function of weight $w$ increases with weight $w$, implying a tighter constraint on the perturbation entries. The weight $w$ is initialized with $\omega$. Table 1 shows the global minima for three values of weight $w$. Figures (a)–(b) correspond to Case 1, and (c)–(d) correspond to Case 2.

Next, we present a comparison of the global minimum obtained by Algorithm 1 for different penalty weights. Table 2 shows the global minima for three values of weight $w$. Further, Fig. 3 shows the sparsity error $E = \|\Delta - 5 \circ \Delta\|$ and norm of the optimal perturbation as a function of weight $w$. The algorithm is initialized with $\omega_{gl}$ and $\omega_{agl}$ for all weights. Observe that as the weight $w$ increases, the sparsity error decreases and optimal perturbations become more sparse. Furthermore, the norm of the optimal perturbations increases with $w$, since a larger weight implies a tighter constraint on the perturbation entries.

Finally, we illustrate that our sparse SR framework provides structural insights into the stability of dynamical networks. We consider symmetric line and circular networks as shown in Fig. 4, where the nodes represent the scalar states and the edges represent the non-zero couplings. All self loops have weight $-2.5$ and all inter-node edges have weight $1$. The weighted incidence matrix $A$ of a network can be easily constructed using these weights, and it is stable.

We are interested in identifying the edge(s) that are most critical for the stability of the network. This can be characterized by assigning a sparsity pattern corresponding to a subset of edges that are perturbed, and computing the sparse SR using the developed framework. Then, the most critical edge set is the one...
which results in the least SR. For the line network, we allow only a single edge to be perturbed. It implies that only one entry of $\Delta$ is allowed to be perturbed. For the circular network, we allow for two inter-node edges to be perturbed (self loop edges are fixed). This implies that only two non-diagonal entries of $\Delta$ are allowed to be perturbed. We set $B = C = I$ for both the networks.

For the line network, we observe that the most critical edge is the self loop of the node in the center of the line (node 4). The critical corresponding to this edge is 1.5118. For the circular network, the two most critical inter-node edges are the edges between any two neighboring nodes. The optimal perturbations for the two edges are 0.9724 and 0.9814 (in any order) and the corresponding SR is 1.3816. Due to the circular symmetry, there exist 7 pairs of critical edges in the network. These examples highlight that our sparse SR framework is useful in studying the robust stability of sparse networks which was not possible using the previous non-sparse SR theory.

6. Conclusion

In this paper we study the real, sparse, $F$-norm stability radius of a linear time-invariant system, which measures its ability to maintain stability in the presence of structured additive perturbations. We formulate the stability radius problem as an equality-constrained minimization problem, and characterize its optimality conditions. These conditions reveal important geometric properties of the stability radius and the associated perturbation, and allow us to design a penalty based Newton descent algorithm that provably converges to locally optimal values of the stability radius and the associated perturbation. Using the Frobenius norm to measure the size of perturbations is not only convenient for the analysis, but it also provides selective information regarding which system entries have a greater effect on system stability. Further, imposing an arbitrary sparsity pattern on the perturbation becomes crucial when studying the stability radius of network systems and, more generally, systems where only a subset of the entries can be perturbed. Numerical examples are shown to highlight the utility of our framework for characterizing structural fragility of networks. Future research directions include the exploration of more efficient, accurate and reliable optimization procedures, especially for large-scale systems.

Appendix. Proof of Lemma 4.1

Part 1 — Gradient: We derive the gradient by expressing the first order differential of $J_W$ in terms of the differential of free variables $d\delta$. Using $J_W = \frac{1}{2}(\text{vec}(W) \circ \delta)^T(\text{vec}(W) \circ \delta) = \frac{1}{2} \delta^T W \delta$, we get

$$dJ_W = \delta^T \delta.$$

Next, we derive an expression for $d\delta$. Taking the differential of $(17a)$ and vectorizing (using $I^T = -I$) yields

$$A(dX) - \omega(dX) - (d\omega)X = -B(dG) \quad (24)$$

$$\Rightarrow A(\omega)dx_v = -Iv, d\omega - Bdg$$

$$\Rightarrow dx_v = -Vd\delta. \quad (25)$$

Vectorizing and combining (19a)–(19b) using P.2 and the relation $\text{vec}(W \circ W \circ \Delta) = W \delta$, we get

$$\bar{X} \delta = \begin{bmatrix} 0 \\ g \end{bmatrix}. \quad (26)$$

Since $\bar{W} > 0$ and $\bar{X}$ is full column rank (Assumption A4), $\bar{X}$ is invertible and (26) has a unique solution. Taking the differential of (26) and using P.2, P.3, P.9, we get

$$\bar{X} \left[ \frac{d\delta}{d\lambda} \right] = \begin{bmatrix} 0 \\ dg \end{bmatrix} - \frac{d\bar{X}}{d\lambda} \left[ \frac{d\delta}{d\lambda} \right] = \begin{bmatrix} 0 \\ d\bar{X} \delta \end{bmatrix}$$

$$= \begin{bmatrix} 0 \\ dg \end{bmatrix} - \begin{bmatrix} \text{vec}(\Lambda(C\delta)^T) \\ \text{vec}(\Delta(C\delta)\delta) \end{bmatrix} = \begin{bmatrix} 0 \\ d\bar{X} \delta \end{bmatrix} - Edx_v$$

$$\Rightarrow d\delta = \begin{bmatrix} I & 0 \end{bmatrix} \delta \quad (27)$$

Next, we have

$$d\delta = \bar{X}^{-1} \delta = Z^T \delta.$$

Substituting $d\delta = Z^T(d\delta)$ in (23) and using P.8, we get the gradient in (21).

Part 2 — Hessian: We derive the Hessian by expressing the second order differential of $J_W$ as $d^2J_W = (d\delta)^T \delta(d\delta)$. Taking the differential of (23), we get

$$d^2J_W = (d\delta)^T \delta(d\delta) + (d\delta)^T W \delta.$$

Using $d\delta = Z^T(d\delta)$ from the first part of the proof, the first term in (28) becomes $(d\delta)^T Z W Z^T(d\delta)$. Next, we compute the second term in (28). Since $G$ and $\omega$ are free variables, their second order derivatives $d^2G$ and $d^2\omega$ are zero (Magnus & Neudecker, 1999). Taking the differential of (24) and vectorizing, we have

$$\bar{A}(d^2X) - \omega(d^2X) - 2(d\omega)X = 0 \quad (P.2)$$

$$\Rightarrow d^2x_v = -2(d\omega) \bar{A}(\omega)^{-1}I(dx_v) \quad (25)$$

Taking the differential of (29), we get

$$\bar{X} \left[ \frac{d^2\delta}{d\lambda^2} \right] = -\bar{X} \left[ \frac{d\delta}{d\lambda} \right] - dEdx_v - Ed^2x_v$$

$$= -Ed^2x_v - 2dEdx_v$$

$$\Rightarrow d^2\delta = \begin{bmatrix} I & 0 \end{bmatrix} \left[ \frac{d^2\delta}{d\lambda^2} \right] = -\begin{bmatrix} I & 0 \end{bmatrix} \bar{X}^{-1}(Ed^2x_v + 2dEdx_v)$$

$$\Rightarrow (d^2)^T W \delta = -(d^2x_v)^T E^T W \delta - 2(dEdx_v)^T E^T \delta. \quad (30)$$
Using (29) and $\delta = e_{2,m+1}^T(d\vec{z})$, the first term on the right side of (30) is
\[-(d^2x_{\cdot})^T F^T U^T W \delta = -2d\vec{z}^T V^T \tilde{A}(\omega)^{-1} F^T U^T W \delta e_{2,m+1}^T(d\vec{z}). \quad (31)\]

The second term on the right side of (30) is
\[-2(d\delta x_{\cdot})^T U^T W \delta\]

Using (29), (30), and (31) in (28), we get
\[d^2J_W = d\vec{z}^T Z \hat{W}^2 \hat{z} d\vec{z} + 2d\hat{z}^T M(d\vec{z}) = (d\vec{z})^T [Z \hat{W}^2 \hat{z} + M + M^T](d\vec{z}). \quad \blacksquare \]

The expression of Hessian $H$ in (22) follows from P.8.
